  Immunologic aspects of ED pregnancies
† Discussion
† Conclusions

Background: Egg donation (ED) makes it possible for subfertile women to conceive. Pregnancies achieved using ED with unrelated donors are unique, since the entire fetal genome is allogeneic to the mother. The aims of this review were to evaluate the consequences of ED pregnancies and to place them in the special context of their atypical immunologic relationships.

Methods: This review comprised an online search of English language publications listed in Pubmed/Medline, up to 29 January 2010. Seventy-nine papers met inclusion criteria. Using the literature and the authors’ own experience, the relevant data on pregnancy outcome and complications, placental pathology and immunology were evaluated.

Results: Multiple studies document that ED pregnancies are associated with a higher incidence of pregnancy-induced hypertension and placental pathology. The incidence of other perinatal complications, such as intrauterine growth restriction, prematurity and congenital malformations, is comparable to conventional IVF. During pregnancy, both local and systemic immunologic changes occur and in ED pregnancies these changes are more pronounced. There is almost no information in the literature on the long-term complications of ED pregnancies for the mother.

Conclusions: ED pregnancies have a higher risk of maternal morbidity. Owing to the high degree of antigenic dissimilarity, ED pregnancies represent an interesting model to study complex immunologic interactions, as the fully allogeneic fetus is not rejected but tolerated by the pregnant woman. Knowledge of the immune system in ED pregnancies has broader significance, as it may also give insight into immunologic aspects of tolerance in solid organ transplantation.

Key words: reproductive immunology / egg donation / oocyte donation / pregnancy outcome / pregnancy complications

Introduction

The first successful pregnancy achieved after egg donation (ED) was reported in 1984 (Lutjen et al., 1984). Since then, thousands of pregnancies after ED have occurred worldwide. The original indication was premature ovarian failure (Bustillo et al., 1984; Sauer et al., 1991). More recent indications include advanced maternal age, diminished ovarian reserve, secondary infertility following treatment of childhood...
Complications and immunologic aspects of egg donation 705

malignancies (Kavic and Sauer, 2001), multiple failed IVF attempts (Klein and Sauer, 2002) and maternally inherited genetic abnormalities (Pados et al., 1994). Infertile women who do not produce euploid embryos also depend upon ED to achieve a successful pregnancy.

Eggs obtained from a suitable donor, either provided by relatives or via independent, sometimes for profit organizations (Gorrill et al., 2001), are fertilized with sperm of the recipient’s partner or donor and the resulting embryos are transferred into the recipient’s uterus. Some pregnancies achieved using ED are unique, since the entire fetal genome is allogeic to the mother. Therefore, ED pregnancies represent an interesting model to study complex immunologic interactions between the fetus and the pregnant woman. Despite a continued increase in the number of ED pregnancies, relatively little is known about the underlying biology and long-term complications of this approach. Similar immunologic interactions exist in surrogate gestations, in which biological motherhood is achieved without pregnancy by transferring fertilized eggs to the uterus of a second woman. The surrogate approach can be used for women without a functioning uterus, or in women for whom pregnancy would be life-threatening (Meniru and Craft, 1997).

Delaying childbirth and the resulting demand for infertility treatment have resulted in ~1% of US infants being conceived through assisted reproduction technologies (ART) (The Practice Committee of the American Society for Reproductive Medicine, 2004). Currently ~10% of the IVF cases in the USA use ED (Sunderam et al., 2009). This has increased the demand for the availability of oocyte donors; in the USA more than 100,000 women have donated their oocytes (Schneider, 2008). In Europe, a recent report showed a total of 11 491 EDs (Nyboe et al., 2009).

ED was initially developed as a therapy for young women with premature ovarian failure, rather than as a means of overcoming the age-related decline in fertility. However, age-related infertility is now one of the most common reasons to use ED, especially in women over 40 years of age (Paulson et al., 2002). The data suggest that fertility depends on oocyte age and quality, and less on uterine age (Borini et al., 1996; Stolwijk et al., 1997; Soares et al., 2005). Some studies report that ED in recipient women of advanced maternal age is as successful in establishing pregnancy as in younger recipients (Borini et al., 1995; Sauer et al., 1996; Abdalla et al., 1997; Paulson et al., 1997). This would suggest that endometrial receptivity is unaltered by age (Paulson et al., 1997, 2002). However, for recipient women in their late 40s and beyond, the success rate of ED starts to decline, so there are likely to be as yet undiscovered factors that are affected by maternal age (Borini et al., 1996; Toner et al., 2002; Soares et al., 2005). Advanced maternal age is almost always inherent to ED; thus it will be a confounding factor in research studies of ED.

Obesity (Belver et al., 2003), an endometrial thickness of <8 mm, and the need for the use of a GnRH analogue to down-regulate the pituitary before endometrial priming all negatively influence pregnancy rates (Dessolle et al., 2009). In contrast, high birth rates have been observed in frozen-thawed embryo replacement cycles in which embryos are derived from cycles that used GnRH analogues (Griesinger et al., 2007). In ED, besides the recipient’s mid-cycle endometrial thickness, the quality of the transferred embryos is also important for a successful pregnancy (Navot et al., 1991; Sauer et al., 1992; Noyes et al., 2001).

**Methods**

The aims of this systematic review were to evaluate the consequences of ED pregnancies and to place the findings in the literature in the special context of their atypical immunologic relationships in ED pregnancies. A search in PubMed, using the Medical Subject Headings terms ‘oocyte donation’ and ‘ED’, in combination with ‘pregnancy outcome’ or ‘pregnancy complications’ or ‘immunology’ or ‘placenta’ was performed. English language was used as a limit. Time was not limited but the search was completed on 29 January 2010. The titles and abstracts of the resulting articles were scanned and evaluated by the first, second and last authors (M.L.P.H., E.E.L.O.L. and S.A.S). Inclusion criteria were original and review articles that focused on current knowledge in ED pregnancies regarding pregnancy outcome and complications, placental pathology and immunologic aspects. In addition, some background articles on reproductive and transplantation immunology were included. Exclusion criteria were: case reports, letters and articles with an exclusive focus on ethics of ED. The main search identified 505 potentially relevant studies. Figure 1 shows the flow chart, which led to the final 79 references included in the review.

**Results**

**Consequences of ED pregnancies**

Many studies of ED pregnancies have focused on perinatal complications, such as pre-eclampsia, the mode of delivery and immediate neonatal problems, such as prematurity. In addition, ethical and medical concerns have been raised regarding the effects of treatment on the donor (Schneider, 2008). With regard to the recipient, most of the emphasis has been on short-term complications of pregnancy, because of the higher incidence of both early and late obstetric problems. The reason for the higher incidence of complications in ED pregnancies is unclear from the literature reviewed.

**Maternal complications**

ED enables women of advanced age to achieve successful pregnancies. However, advanced maternal age leads to potential medical and obstetric complications. Pregnant recipients above the age of 40 years are at an increased risk for gestational diabetes, pre-eclampsia and thrombophlebitis (Michalas et al., 1996); above the age of 45 years they are at an increased risk of hypertension, proteinuria, premature rupture of membranes, second- and third trimester haemorrhage, preterm delivery and lower mean infant birthweights (Soares et al., 2005; Simchen et al., 2006). One study that corrected for maternal age and multiple gestation concluded that women who conceived with donor oocytes remain at high risk for preterm labour, pre-eclampsia and protracted labour, requiring Caesarean section delivery (Henne et al., 2007). The rate of Caesarean section deliveries in ED pregnancies is increased compared with spontaneous conceptions, and is reported to range from 40 to 76% of cases (Blanchette, 1993; Sauer et al., 1996; Abdalla et al., 1998; Soderstrom-Antila et al., 1998a, b; Yaron et al., 1998; Kavic and Sauer, 2001; Klein and Sauer, 2002; Sheffer-Mimouni et al., 2002).

**Pregnancy-induced hypertension**

ED pregnancies are associated with a higher than expected incidence of pregnancy-induced hypertension (PIH), ranging from 16 to 40% of cases (Serhal and Craft, 1989; Blanchette, 1993; Abdalla et al., 1998;
Soderstrom-Anttila et al., 1998a, b; Salha et al., 1999; Sauer, 2001; Klein and Sauer, 2002; Sheffer-Mimouni et al., 2002; Wiggins and Main, 2005), most likely resulting from a higher incidence of placental pathology (Pados et al., 1994). It has been suggested that the increased rate of hypertension in ED pregnancies is related to advanced maternal age, nulliparity and ovarian failure (Pados et al., 1994), since these factors are associated with multiple obstetric complications (Krieg et al., 2008). However, a study by Sheffer-Mimouni et al. (2002) found that these factors were not independent risk factors for PIH and they concluded that the higher incidence of PIH in ED pregnancies is a result of an altered immune response. In another report, an increased risk for PIH was observed in women with ED pregnancies in women <35 years or ≥40 years of age (Keegan et al., 2007).

In the studies above, the control groups were spontaneously conceived pregnancies. Since IVF pregnancies are associated with more obstetric complications than naturally conceived pregnancies (Allen et al., 2006), they represent a more appropriate control group to examine the consequences of ED. Wiggins and Main (2005) found a 3-fold increased incidence of hypertensive complications in ED compared with standard IVF pregnancies (26 versus 8%, respectively, \(P = 0.02\)). For nulliparous women this difference was even more significant, with 37% of the ED group and 8% of the standard IVF group affected by hypertension \((P < 0.003)\). Multiple logistic regression analysis in nulliparous patients showed an odds ratio (OR) of 7.1 \((P = 0.019)\). In singleton and twin pregnancies, the same effect was found (OR: 4.9, \(P = 0.017\)). Maternal age was not an added risk factor for the development of PIH (OR: 1.0) (Wiggins and Main, 2005). Interestingly, the incidence of PIH appears to be significantly higher if the oocyte donor is unrelated to the recipient (20 versus 3.7% for standard IVF, \(P = 0.03\)), versus a related, sibling donor (8 versus 3.7% for standard IVF, \(P = 0.31\)) (Kim et al., 2005): this study retrospectively analysed 61 ED pregnancies that were classified into two subgroups according to the relationship between the ED and recipient, and 127 non-donor IVF pregnancies. The groups were matched for age, parity and number of fetuses. The Kim et al. (2005) study is the only one that has specifically examined the immunogenetic origin of the egg and its relationship to complications of pregnancy. These data suggest that PIH is more frequent when ED involves an immunologically unrelated donor.

**Bleeding**

A possible result of the unique, non-physiological immunologic relationship between the fertilized oocyte and the maternal decidua is shallower placental invasion (Dekker et al., 1998; Moffett and Loke, 2006). The higher incidence of bleeding complications in the first trimester could be related to this insufficient placenta. On the other hand, excessive invasion might result in more post-partum haemorrhage in ED pregnancies as a result of placenta praevia or abnormal placentation (Sheffer-Mimouni et al., 2002).

---

**Figure 1** Flow chart depicting selection of articles for systematic review of ED pregnancies.
The incidence of first trimester vaginal bleeding is increased in ED pregnancies, ranging from 12 to 53% of cases (Pados et al., 1994; Abdalla et al., 1998; Soderstrom-Anttila et al., 1998a, b). Significant blood loss is estimated to occur in 43–53% of first trimester cases (Soderstrom-Anttila et al., 1998a, b; Sheffer-Mimouni et al., 2002) and 6% of second trimester cases (Pados et al., 1994; Sheffer-Mimouni et al., 2002). The incidence of first trimester bleeding is substantially higher if compared with standard IVF pregnancies (Soderstrom-Anttila et al., 1998a, b) and second trimester bleeding is higher if compared with the spontaneously conceived population (<1%) (Liptz et al., 1991). It has been assumed that more bleeding complications are associated with multiple implantation sites and early fetal loss (Shaw and Sauer, 1995). However, in ED cases in which only two oocytes per cycle are transferred, the frequency of bleeding still remains high (Soderstrom-Anttila et al., 1998a, b). Other explanations, such as endometrial preparation therapy, have been suggested, but a possible relationship between various steroid replacement regimens and first trimester bleeding is difficult to assess.

Long-term consequences

The study of the trafficking of intact fetal cells into the maternal circulation (fetal cell microchimerism) is relevant to ED pregnancies, because it is not yet known if these circulating fetal cells play a role in establishing or maintaining tolerance to the conceptus. This merits further investigation. Furthermore, the consequences of the persistence of foreign circulating fetal cells for the mother’s long-term health are currently unknown. In one study, however, allogeneic male fetal cells were shown to persist for up to 9 years in the circulation of healthy post-partum women who conceived using egg donors and delivered male infants (Williams et al., 2009). The implications of becoming microchimeric with an unmatched population of fetal progenitor cells are an area for future research.

ED conception is often omitted from the mother’s and the baby’s medical records, so correlations between ED and specific adverse outcomes are difficult to make. In ~40–50% of the cases the fact that it was an ED pregnancy is never disclosed to the child or other family members (Wen, 2008). The literature search revealed no studies evaluating long-term effects of ED for the mother. Long-term outcome studies are therefore warranted (Kramer et al., 2009).

Fetal and neonatal complications

In most studies that assessed the obstetric outcome after ED relatively little has been reported on fetal and/or neonatal complications. Elevated risks (relative to the general population) are primarily related to the higher incidence of multiple gestation (Pados et al., 1994; Sauer and Kavic, 2006). The incidence of intrauterine growth restriction is also not increased compared with the general population (Soderstrom-Anttila et al., 1998a, b). The incidence of preterm deliveries in ED singleton pregnancies (10.6%) is not increased if compared with the general population (Soderstrom-Anttila et al., 1998a, b; Yaron et al., 1998). Significantly, there appears to be no effect of ED pregnancy (with or without PH) on neonatal birthweight (Sauer et al., 1996; Soderstrom-Anttila et al., 1998a, b). The general health status of children under 5 years old who were conceived using ED is at least as good as that of children conceived using standard IVF procedures (Soderstrom-Anttila et al., 1998a, b). There is also no increase in the incidence of congenital malformations in infants resulting from ED pregnancies (Yaron et al., 1998; Sheffer-Mimouni et al., 2002).

Placental pathology

At the fetal–maternal interface significant histological and immunohistological differences are present when comparing ED and non-donor IVF pregnancies. Characteristic pathologic findings in ED cases include a higher incidence of villitis of unknown etiology, chronic deciduitis, massive chronic intervillitis, maternal.floor infarction and ischemic changes, as seen with pre-eclampsia (Styer et al., 2003; Perni et al., 2005; Gundogan et al., 2009) (Fig. 2). The chronic deciduitis observed in ED placentas is characterized by its severity and the presence of a dense, fibrinoid deposition in the basal plate. Furthermore, an increased infiltration of CD4+ T-helper cells and CD56+ natural killer (NK) cells is present in the basal plate of ED placentas (Gundogan et al., 2009). It is in the basal plate where extravillous trophoblast (of fetal origin) interfaces with and invades the maternal tissue. The extravillous trophoblast cells do not express classical HLA-A and HLA-B molecules, thereby preventing interaction with cytotoxic T cells. However, they do express a unique combination of HLA antigens (HLA-C and the non-classical HLA-E and HLA-G) that interact with KIR receptors on uterine NK cells (Hiby et al., 2004; Diet et al., 2006; Sargent et al., 2006), although HLA-C can also serve as a target molecule for CD8+ T-cells (Tilburgs et al., 2009a, b). The striking findings of a dense fibrinoid deposition and mononuclear cell infiltration in the basal plate suggest that the placental abnormalities are related to an immune-mediated response that is more pronounced in ED pregnancies. The placental damage may be the consequence of a type of graft-versus-host disease and/or organ rejection type of reaction (Gundogan et al., 2009).

Immunologic aspects of ED pregnancies

Normal fetal-maternal immunology

A successful pregnancy is an interesting immunologic paradox. The fetus carries paternal and maternal genes but is not rejected by the maternal immune system, over a period of 9 months (Fig. 3). In spontaneously conceived gestations, several specific protective mechanisms have been postulated to explain the maternal tolerance of the fetus. Since the fetal tissue is directly exposed to the maternal blood, it is at risk of being attacked by components of both the innate and acquired immune system, with the potential risk of death. Therefore, to develop tolerance to the fetus, humans need an immune privileged site at the fetal–maternal interface in order to reproduce (Girardi et al., 2006). In spontaneously conceived pregnancies, immune recognition of the semi-allogeneic fetus takes place, but the soluble and cellular components of the maternal immune system are kept under control (or are locally down-regulated), leading to a maternal immune system that favours implantation of the embryo (Le Bouteiller et al., 2003). The currently accepted view is that a successful pregnancy depends on an appropriate balance of the different components of the maternal immune system, with predominance of T helper 2 immunity (Wegmann et al., 1993; Saito et al., 1999, 2007; Saito and Sakai, 2003). At the human fetal–maternal interface, maternal recognition of fetal antigens presented by trophoblast cells or by fetal cells trafficking into the maternal circulation is essential for the induction of immunoregulatory mechanisms (Sindram-Trujillo et al., 2003). It
Figure 2 Photomicroscopic images of placentas from ED and spontaneously conceived pregnancies. (Sections stained with hematoxylin and eosin, all original magnification ×400.) (A) Decidua basalis of ED pregnancy placenta with deciduitis illustrated by the infiltration of mononuclear cells (arrow). (B) Normal decidua basalis from a spontaneously conceived pregnancy with normal decidual cells (arrow). (C) Villi from an ED pregnancy placenta. The stromal cellularity is increased by an infiltrate of mononuclear cells (arrow). (D) Villi of a spontaneously conceived pregnancy placenta.

Figure 3 Schematic of the inheritance of the most immunogenic HLA-antigens in a spontaneously conceived and an ED pregnancy. (A) In a spontaneously conceived (or non-donor IVF) pregnancy the child inherits antigens of the father and antigens of the mother. The five most immunogenic HLA antigens (HLA-A, -B, -C, -DR and -DQ) are depicted in orange for the mother and in blue for the father. The child inherits one set from the mother and one set from the father. Comparing the antigens of the child with the mother a maximum of five mismatches is possible (dashed line). (B) In an ED pregnancy involving an unrelated donor, no antigens from the mother are present in the fetus. The antigens of the donor are depicted in green and the antigens from the father in blue. The set of genes inherited by the child contains no antigens of the mother; therefore, a maximum of 10 mismatches is possible between the mother and the child in an ED pregnancy (dashed line).
apparent that activated T cells at the maternal interface include regulatory T cells (Sindram-Trujillo et al., 2003; Tilburgs et al., 2006). These regulatory T cells have an important role in the local down-regulation of human fetal-specific allogeneic T cell responses (Tilburgs et al., 2008). All of these protective mechanisms maintain the immunosuppressive environment in the pregnant uterus, and in this way the semi-allogeneic fetus is capable of surviving in the uterus.

**Parallels with blood transfusions**

The mechanism(s) involved in the effective down-regulation of the maternal immune response to the semi-allogeneic fetus can be compared with the ones involved in the development of tolerance by pre-transplant blood transfusions. Blood transfusions have an immunomodulating effect, as demonstrated by the positive association of kidney graft survival and the number of allogeneic transfusions (Opelz et al., 1973). In addition, a beneficial effect of HLA-DR matched transfusions has been shown in kidney (Lagaaj et al., 1989) and heart (van der Mast and Balk, 1997) transplantation. Furthermore, more HLA alloantibodies are formed after HLA mismatched transfusions compared with HLA-DR shared transfusions (Bayle et al., 1995). Down-regulation of the immune response may occur by the induction of regulatory CD4+ T-cells, which are induced when the donor and recipient share at least one HLA-class II molecule (Claas et al., 2001). This immunomodulating effect only occurs in the case of blood transfusions which are semi-allogeneic or involve one shared HLA-DR. Blood transfusions that are fully HLA mismatched with the recipient lead to immunization, rather than tolerance of the patient.

**Immune studies in ED**

Although other mechanisms can be involved, it is likely that down-regulation of the maternal alloimmune response to the fetus in an ED pregnancy is far more difficult than in spontaneously conceived pregnancies with semi-allogeneic fetuses. Compared with spontaneously conceived pregnancies, there is a higher degree of antigenic dissimilarity in ED cases. If the five most immunogenic HLA antigens (HLA-A, -B, -C, -DR and -DQ) are taken into consideration, the maximal number of mismatches in spontaneous conceived pregnancies would be 5. In ED pregnancies this could reach a maximum of 10 mismatches (Fig. 3). Since ED pregnancies are characterized by more HLA mismatches, it is to be expected that a possible relationship between aspects of immune regulation and the number of HLA mismatches will become more apparent in ED pregnancies. In pregnant women who conceived by ED, an increased percentage of intracellular interferon-γ (Th1, also involved in spiral artery formation) and interleukin-4 (Th2)-positive CD4+ T-lymphocytes was found in peripheral blood compared with pregnant women after spontaneous conception (Chernyshov et al., 2008). This hyperactivation of Th1 and Th2 cells, induced by the allogeneic fetus, is specific for ED pregnancies. This suggests that the additional mechanism of Th2 immunity in ED pregnancies helps contribute to a successful pregnancy, even with a completely allogeneic fetus. Although the Chernyshov et al. (2008) study investigated immune cells in the peripheral blood, the widely accepted view is that the active immune mechanisms take place at the fetal–maternal interface; therefore, it is possible that an effect will be even more prominent at this location. Recently, a significant correlation between the extent of HLA mismatches and the percentage of CD4+CD25dim activated T-cells in the decidua parietalis of uncomplicated pregnancies was described (Tilburgs et al., 2009a, b).

In spontaneously conceived pregnancies, the correlation between the number of amino acid triplet sequence (HLA epitope) mismatches between pregnant women and their children, and antibody production in the pregnant woman against the paternal antigens inherited by the child has been studied (Dankers et al., 2004). A positive correlation was found between the number of triplet mismatches (0–22) and the percentage of women producing HLA antibodies (P < 0.001). If no triplet mismatches were present, no antibodies were formed, even in the case of one or two classical HLA antigen mismatches. It remains to be established whether the actual number of HLA mismatches, or epitope mismatches, is more important in establishing tolerance to the fetus. However, it is likely that in ED pregnancies, the number of both HLA antigen and epitope mismatches will be even higher than in spontaneously conceived pregnancies, therefore the percentage of women producing antibodies will be higher, and this may have clinical implications.

The immune system clearly plays an important role in ED pregnancies. Unfortunately, there is a lack of information from the mother’s perspective about the long-term effects of exposure to foreign cells and antigens in the recipient, since the usual clinical end-point is the chance of having a take-home baby. From the literature it is unknown at present whether, later in life, the consequences of having conceived using ED may be harmful or not. In addition, when investigating immunologic aspects of ED pregnancies it is important to analyse the underlying reason why ED was necessary. For example, it is accepted that premature ovarian failure is a heterogeneous disorder in which some of the idiopathic forms are based on abnormal self-recognition by the immune system (Hoek et al., 1997). It is possible that the pre-existing immunologic mechanisms involved in premature ovarian failure may contribute to the immunologic differences between ED and spontaneously conceived pregnancies.

**Discussion**

Although ED gives infertile women the opportunity to conceive, it may lead to harmful consequences during pregnancy if compared with spontaneously conceived pregnancies. This review gave an overview of the consequences of ED pregnancies with respect to their atypical fetal-maternal immunologic relationships. Review of the literature showed that women who conceived by ED have an increased risk of PIH (Serhal and Craft, 1989; Blanchette, 1993; Abdalla et al., 1998; Soderstrom-Anttila et al., 1998a, b; Salha et al., 1999; Sauer, 2001; Klein and Sauer, 2002; Sheffer-Mimouni et al., 2002; Wiggins and Main, 2005; Keegan et al., 2007), an increased rate of Caesarean section deliveries (Blanchette, 1993; Sauer et al., 1996; Abdalla et al., 1998; Soderstrom-Anttila et al., 1998a, b; Yaron et al., 1998; Kavic and Sauer, 2001; Klein and Sauer, 2002; Sheffer-Mimouni et al., 2002), an increased risk of post-partum haemorrhage (Sheffer-Mimouni et al., 2002), and an increased risk of first trimester vaginal bleeding (Pados et al., 1994; Abdalla et al., 1998; Soderstrom-Anttila et al., 1998a, b). All of these complications can be the consequence of ED pregnancies; however, other factors that correlate with infertility and age could also be an underlying cause. For example, women...
Conceiving through ED are more often primigravidae and more frequently have ovarian failure compared with women who conceive spontaneously; these factors are all associated with obstetric complications (Krieg et al., 2008). More studies that correct for these confounding variables (e.g. maternal age, nulliparity and ovarian failure) are needed to determine the specific role that ED plays in these important obstetric complications. The higher risk of maternal morbidity in women who conceived through ED is a limitation of this form of treatment for infertility. For the benefits to outweigh the risks it might be important to select low risk donor-recipient combinations. The egg donors should be <35 years old (Faber et al., 1997) and unaffected by infectious diseases or hereditary syndromes (Shulman et al., 1999; Klein and Sauer, 2002). Considering the immunologic mechanisms in ED, it might be worthwhile to perform HLA-typing of donor and recipient in order to select haplo-identical combinations that would be more comparable to spontaneously conceived pregnancies than fully HLA mismatched combinations.

Although the literature conclusively demonstrates an increased risk of ED-related pregnancy complications for the mother, it does not show an increased complication rate for the fetus or newborn (Sauer et al., 1996; Soderstrom-Anttila et al., 1998a, b; Yaron et al., 1998; Sheffer-Mimouni et al., 2002). Since there is a general lack of studies on the long-term outcome of ED pregnancies, it is currently unknown whether the child or mother experiences any consequences later in life. It is therefore important to document ED conception in the medical record to evaluate the subsequent consequences of carrying an allogeneic fetus. In ED pregnancy, the mother is exposed to foreign cells and antigens, a situation that is comparable to blood transfusions and organ transplantation. ED pregnancy leads to a hyperactivation of TH1 and TH2 cells compared with spontaneously conceived pregnancies (Chernyshov et al., 2008). This suggests that the allogeneic fetus induces an additional mechanism that contributes to a successful pregnancy. It is possible that these mechanisms may have consequences later in life. Therefore, long-term follow-up studies are strongly recommended.

Conclusions

ED provides a valuable addition to the list of treatment options for women who require ART. The benefits of having a take-home baby are counter-balanced by the higher risk of maternal morbidity. The increased rate of complications may be related to the allogeneic nature of the fetus. To understand the underlying mechanism(s) of acceptance of the allogeneic fetus, more research regarding the unique immunologic aspects of ED pregnancies is warranted. Understanding the role of the immune system in successful ED pregnancies also has broader biomedical significance in that it may also give insight into immune mechanisms leading to immunologic tolerance for HLA mismatched solid organ transplants.
